ABSTRACT

This work demonstrates the applicability of red mud-reduced graphene oxide (RM-rGO) nanocomposites, for the reliable and selective electrochemical detection of arsenic. The new nanocomposite material shows excellent anti-interference activity towards the arsenic ions (As³⁺) with the co-occurrence of other common cations (Cd²⁺, Cr²⁺, Zn²⁺, Pb²⁺, and Hg²⁺). Especially, the nanocomposite is exceptionally selective for As³⁺ in the presence of Cu²⁺ ions, which is stated to be the main interfering agent in the electrochemical detection of As³⁺. Under optimal experimental conditions, the new nanocomposite displays a high sensitivity (2.49 μA/ppb) as well as a very low detection limit (0.07 ppb) towards As³⁺ detection. This excellent electrochemical performance of the composite is accounted for the high adsorption proficiency of hematite (Fe₂O₃) phase rich nano red mud particles and enhanced electron transfer kinetics due to the presence of rGO.

KEYWORDS: Red mud, arsenic, hematite, electrochemical detection, sensitivity, electron transfer kinetics.

INTRODUCTION

Arsenic ion (As³⁺), a highly toxic substance, widely distributed in nature and one of the most abundant mineral in the earth's crust.¹² According to the World Health Organization (WHO), the maximum acceptable level of As³⁺ in drinking water is 10 ppb and around 20 countries are suffering from serious As³⁺ contamination.³ The determination of trace level (sub ppb) of As³⁺ in natural water (ocean, sea, rivers), wastewater (from mining, metal processing, pesticides, organic

chemicals, etc.) and drinking water has become very important because these media are vulnerable to As^{3+} contamination.⁴ Among many developed methods for toxic metal ions detection,^{5,6} electrochemical (EC) techniques especially, low-cost stripping voltammetry has gained considerable interest in terms of sensitivity, portability, rapid analysis time and suitable for on-site detection.^{7,8} The performance of such methods, however, depends heavily on the materials used for detection purposes.

Over the decades metal oxide nanoparticles (NPs) with their strong adsorption ability or electrocatalytic activity against toxic metal ions were explored to improve the EC sensor technology.^{9–12} However, owing to the electrode fouling and inferior electrical conductivity, most of the metal oxide NPs suffer from long-term stability and unfavorable electron transfer kinetics.¹³ On the other hand, graphene and its associates (graphene oxide/reduced graphene oxide) have gained significant attention in the field of electrochemistry, due to their tunable electrical conductivity, high electron mobility, and large surface area.^{14–16} The combination of graphene with metal oxide NPs can, therefore, overcome the drawbacks present in the metal oxides and can provide a modern EC platform for the detection of toxic metal ions. Up to now Fe_3O_4 , Fe_2O_3 , MnO_2 , PbO based graphene nanocomposites (NCs) have been utilized with great success for As^{3+} detection.^{17–19} Among these metal oxides, environmental friendly $\text{Fe}_3\text{O}_4/\text{Fe}_2\text{O}_3$ NPs or nanosheets have shown a higher affinity towards As^{3+} .⁷ But sophisticated synthesis protocols of such NCs lead to an increase in the material production cost. Therefore, a facile approach to prepare low-cost NCs, consist of graphene and many metal oxide phases could be of great significance in the field of EC sensor.

Red mud (RM) is an aluminum industry waste, composed of fine particles containing Fe_2O_3 (30–60%) constitutes; in addition, other metal oxides like Al_2O_3 , SiO_2 , TiO_2 are also present.²⁰ It possesses large surface areas and available at large scale at practically no cost. However, it is highly alkaline in nature and now is a threat to the ecosystem due to the high volume of RM production, processing, and maintenance. RM is well known to have high adsorption capacity towards toxic metal ions and it has been used for the removal of these environmental carcinogens for decades.²¹ Interestingly, the applicability of red mud as an EC sensor towards toxic metal ion detection has not been explored yet.

Thus motivated by the need for a cost-effective, robust, environmental friendly sensor for As^{3+} detection in water and to utilize the excellent adsorption capabilities of RM, herein we report the applicability of RM-reduced graphene oxide (RM-rGO) NCs for As^{3+} detection using square wave anodic stripping voltammetry (SWASV) technique. The evaluation of EC studies of the new NCs exhibit excellent limit of detection (LOD), sensitivity and anti-interference activity towards As^{3+} ions.

EXPERIMENTAL SECTION

RM was collected from National Aluminum Company Limited (NALCO), India. All chemicals including, graphite flakes (>99% Alfa Aesar), sulphuric acid (98%, Fisher Scientific) and hydrochloric acid (37%, Fisher Scientific), potassium permanganate (>99%, Sigma Aldrich), sodium hydroxide (98%, Fisher Scientific), L-ascorbic acid (99%, Sigma Aldrich), potassium ferrocyanide ($\text{K}_4[\text{Fe}(\text{CN})_6]$), potassium ferricyanide ($\text{K}_3[\text{Fe}(\text{CN})_6]$), potassium chloride (KCl) (Fisher Scientific) were used as received without any further purification. A stock solution (1 g/L) of As^{3+} was prepared by dissolving the required quantity of As_2O_3 in NaOH solution, and subsequently, the pH of the solution was adjusted to 3 with concentrated HCl. For interference study, the standard solutions of Cd^{2+} , Cr^{2+} , Zn^{2+} , Cu^{2+} , Pb^{2+} , Hg^{2+} ions (1000 ppm each) were purchased from Sigma Aldrich and were diluted to make a solution of the desired concentration.

First, rGO was synthesized using sonication assisted oxidation of graphite in an acidic environment as reported by Sina Abdolhosseinzadeh et al.²² In order to prepare the nano RM-rGO composite, mechanical milling process using a planetary ball mill (Retsch, PM200) was employed. The powders (mass ratio of RM to rGO is 10:1) were placed in a chrome steel bowl (volume 60 mL) filled with steel balls of diameter 5 mm with balls-to-powder mass ratio was 10:1. The ball milling was carried out at 150 revolutions per minute (rpm) and was continued up to 12 hr. with intermediate intervals of 2 hr. The prepared samples are designated as RM-rGO_Z NCs where Z is the milling hour.

X-ray diffraction (XRD) experiments were performed using Bruker, D8-discover with Cu- K_α energy ($\lambda = 0.154 \text{ nm}$). The Raman spectra were recorded using a Renishaw Raman spectrometer (inVia) using a 532 nm Laser source, using a nominal power of 25 mW for 60 s, 50 $\times$ magnification. Fourier transform infrared spectroscopy was performed using Thermo Scientific NicoletTMiSTM5 FTIR with a diamond ATR accessory. Scanning electron microscopy was carried out using a Hitachi SU5000, with an acceleration voltage of 10 kV and working distance $\square$ 6 mm. All EC

1 measurements were done using the Autolab potentiostat/galvanostat 302N instrument (Metrohm
2 Autolab B.V. Utrecht, Netherlands) controlled by NOVA software.

3 4 **RESULTS AND DISCUSSION**

5
6 Morphology of the RM, rGO and RM-rGOz NCs can be visualized in SEM images (Figure
7 1). In case of rGO, an aggregated and crumpled paper-like structure is observed in Figure 1a, which
8 is a common characteristic of oxidation/reduction processed rGO.²² Whereas, RM particles (Figure
9 1b) are expressing their characteristics feature of irregular size and shape with particle sizes are
10 ranging from 3 to 5 μm . while their agglomerates are distributed within tens of micrometer range.
11 Figure 1(c-e) shows clear changes in the morphology in the RM-rGO NCs caused by ball milling.
12 During the first four hours of ball milling cold welding and cracking mechanism together
13 participate in the formation of spherical size particles.²³ Increasing milling time increases structural
14 disorder, decreases particle size and peel off graphene layers. After 8 hours of milling period,
15 considerable refinement and reduction in particle size is evident. With further increasing the
16 milling time, the particles are being fragmented into more tiny particles and particles tend to
17 agglomerate again. This simple and facile strategy to prepare NPs from particles of micron size
18 has a direct impact on their EC performances, which is discussed next.

Figure 1 SEM images of (a) rGO (b) RM (c) RM-rGO₄ (d) RM-rGO₈ and (e) RM-rGO₁₂.

In order to investigate the charge transfer kinetics of the prepared NCs, cyclic voltammetry (CV) measurements were performed using an EC redox couple ($[\text{Fe}(\text{CN})_6]^{3-/4-}$ in 0.1M KCl), which is displayed in Figure 2a. It is well known that both the degree of reversibility and the charge transfer kinetics, can be improved by eliminating oxygen-containing groups or by increasing the fraction of sp^2 bonded carbons in carbon-based NCs.²⁴ In our case, the smallest $\Delta E_p \approx 0.15$ V (anodic and cathodic peak potential separation) and the highest peak current is observed for RM/rGO₈ NCs. Further, the ratio of anodic to cathodic peak current (i_{pa}/i_{pc}) is calculated as 1.08 for RM/rGO₈, indicating a reversible electron transfer process of the $\text{Fe}^{2+}/\text{Fe}^{3+}$ species. The CV output of RM/rGO₁₂ is also comparable to that of RM/rGO₈. From the scan rate dependency CV curves of RM/rGO₈ (inset of Figure 2a), it can be visualized that redox peak currents (i_{pa} and i_{pc}) are increases linearly with the square root of scan rate (insets of Figure 2a), implies diffusion-controlled redox kinetics of the $\text{Fe}^{2+}/\text{Fe}^{3+}$ species. The CV performance of RM-rGO₂, RM-rGO₆, and RM-rGO₁₀ is also represented in Figure S1. The CV output of RM-rGO₆ and RM-rGO₁₀ are approximately equal to that of RM-rGO₄ and RM-rGO₁₂ respectively whereas, the lowest peak current is observed for RM-rGO₂.

Figure 2b represents the SWASV analytical characteristics of GCE, RM and all RM-rGO NCs where electrodeposition is carried out for 200 s at -0.4 V. Nearly no oxidation peak is observed for the bare GCE electrode. For RM particles there is only a weak peak can be seen. This is probably due to the inferior electrical conductivity of the RM. However, the RM-rGO NCs provide a much greater and sharper peak current response towards the As^{3+} ions. Figure 2b clearly shows that RM-rGO₈ outperforms the other electrodes in terms of stripping peak current response corresponds to the oxidation of As^0 . RM-rGO₈ is, therefore, best suited for As^{3+} detection which results in better sensitivity.

Figure 2 (a) CV response of (i) GCE (ii) RM (iii) RM-rGO₄ (iv) RM-rGO₈ and (v) RM-rGO₁₂ with insets showing the CV response of RM-rGO₈ with scan rate 20, 40, 60, 80 and 100 mVs⁻¹ and the variation of the anodic and cathodic peak current of RM-rGO₈ as a function of scan rate. (b) SWASV response of (i) GCE (ii) RM (iii) RM-rGO₄ (iv) RM-rGO₈ and (v) RM-rGO₁₂ for the detection of 10 ppb As³⁺ ions. The SWASV experimental parameters are as follows: deposition time 200 s, deposition potential -0.4 V, amplitude 25 mV, step potential 4 mV and frequency 25 Hz.

Next, experimental parameters (deposition potential and time) of SWASV experiment are optimized (Figure S2) to achieve the maximum sensing efficiency using RM-rGO₈ NCs. Finally, the detection of As³⁺ is accomplished under the optimized experimental conditions (deposition potential of -0.4 V and deposition time 200 s). Figure 3a represents the SWASV response for As³⁺ at various concentrations. The electrooxidation current was linear within the concentration range of 0.5 to 3.7 ppb (inset of Figure 3a) and the fitted linear relationship between the stripping peak current (corresponds to the oxidation of As⁰ - As³⁺) and concentration of As³⁺ is described by the following equation $i/\mu\text{A} = -0.59 + 2.49c/\text{ppb}$. The limit of detection (LOD) and sensitivity value was found to be 0.07 ppb and 2.49 $\mu\text{A ppb}^{-1}$ respectively. Where LOD is defined as the, lowest quantity of analyte that provides a signal which is significantly different from the blank value with a stated confidence level of 90% and the LOD value is calculated according to the literature reported.²⁵ The obtained LOD value is well below the WHO toxicity mark (10 ppb).³ A comparative study of the performance of the RM-rGO₈/GCE electrode with other sensing platforms developed for EC detection of As³⁺ is summarized in Table 1.

To validate the selectivity of the RM-rGO₈/GCE electrode with the co-occurrence of As³⁺ and Cu²⁺ ions, SWASV measurements were carried out again in a mixture of both the ions where the concentration of Cu²⁺ was kept higher than 8 ppb. Figure 3b represents the SWASV plots of simultaneous detection of As³⁺ and Cu²⁺. An isolated anodic peak corresponding to the oxidation of Cu⁰ - Cu²⁺ is observed at around 0.3 V which is far away (~ 400 mV) from the anodic peak potential of As⁰. Here the concentration of As³⁺ and Cu²⁺ is increased simultaneously and the obtained sensitivity of As³⁺ is marginally improved compared to that observed in the absence of Cu²⁺. The enhanced sensitivity of As³⁺ can be explained on the basis of interference between As³⁺ and Cu²⁺ ions. The stripping peak potentials of both the ions are far from each other (400 mV) and the formation of an intermetallic compound is most unlikely, but small peaks in between As³⁺ and Cu²⁺ are visible which may be due to the formation of As-Cu intermetallic compound during the simultaneous existence arsenic and copper. Such kinds of observations are well documented and

have been published before.²⁶ The influence of other metal ions on the stripping current response of As^{3+} has been further demonstrated by doing interference experiments.

Figure 3 (a) SWASV response of RM-rGO₈ towards the detection of As^{3+} ions over a concentration range of 0.5 to 3.7 ppb. The inset of Figure (a) displays the linear calibration plot of the peak current as a function of As^{3+} ions concentration. (b) SWASV response of RM-rGO₈ for the simultaneous detection of As^{3+} (0.1 to 18 ppb) and Cu^{2+} (8 to 80 ppb) with insets show the linear calibration plots corresponding to the As^{3+} and Cu^{2+} ions concentration.

Table 1. Comparison of our proposed electrode material with other sensing platforms.

Electrode material	Sensitivity ($\mu\text{A/ppb}$)	LOD (ppb)	Ref.

Graphene/ PbO composite	-	0.74	17
RM-rGO composite	2.49	0.07	Present work

Analysis of As^{3+} in the presence of other interfering agent is still difficult, as coexisting substances are co-deposited and stripped with As^{3+} . Therefore selective detection of As^{3+} in the presence of other metal ions is also important. In order to investigate the anti-interference ability

of the RM-rGO₈/GCE electrode, SWASV measurements are recorded in 10 ppb As³⁺ solution in the presence of a 10 fold higher concentration of other metal ions namely Cd²⁺, Cr²⁺, Zn²⁺, Cu²⁺, Pb²⁺, and Hg²⁺. Figure 4 illustrates the anodic stripping current of the As³⁺ in the absence and presence of the above mentioned interfering metal ions. No significant interference is observed of these ions on the As³⁺ stripping current response. The optimized deposition potential (-0.4 V) eliminates the possible interference from common metal cations.¹⁹ In addition, rapid mass transportation in the electrode surface with a small diffusion layer and high current density could also be responsible for such good anti-interference activity. This interference study laid the foundation for reliable and selective As³⁺ detection in water.

Figure 4 Effect of interfering ions Cd²⁺, Cr²⁺, Zn²⁺, Cu²⁺, Pb²⁺, and Hg²⁺ on the stripping current response of 10 ppb As³⁺.

To demonstrate the compatibility of RM-rGO₈ NCs with the Au electrode, similar SWASV tests are conducted on the RM-rGO₈ modified Au electrode (RM-rGO₈/Au) having a physical size (diameter = 2 mm) equal to GCE. Figure S3 (supporting information) displays the typical SWASV curves for the As³⁺ (0.1 to 2.1 ppb) detection with inset represents the linear calibration plot. Interestingly, the anodic peak corresponds to the oxidation of As⁰ - As³⁺ occurs around (0.2 V) which is more positive as compared to the RM-rGO₈ modified GCE electrode. The obtained sensitivity and LOD are found to be 4.35 μA ppb⁻¹ and 0.08 ppb respectively. Though the RM-rGO₈/Au electrode affords better sensitivity compared to RM-rGO₈/GCE, it is still prone to

1 interference from other metal ions, in particular from Cu^{2+} ions, which has a redox potential
2 (around 0.338 V) very near to the oxidation potential of As^0 .

3 Metal oxide nanomaterials are prone to instability under acidic media, hence taking the
4 practical applications into account the reproducibility and stability test of the RM-rGO₈ NCs is
5 carried out in acidic conditions. A series of 6-time repetitive measurements of SWASV response
6 for 2 ppb of As^{3+} is recorded and the results are displayed in Figure S4. The stripping current
7 response of the RM-rGO₈ electrode is highly reproducible with a relative standard deviation of
8 3.57%. The nanocomposite's stability is also investigated and the SWASV current response
9 corresponds to the arsenic oxidation remaining $\square 90\%$ of its initial response after 15 days.
10 Therefore, the good electrode stability and reproducibility for repetitive measurements of As^{3+} ions
11 indicate that the nanocomposite possesses great potential for monitoring As^{3+} ions in real samples.

12 In order to examine the practical application of the present NC (RM-rGO₈), the SWASV
13 experiment has been performed on the real water sample. The sample was collected from the
14 groundwater near Asansol city, West Bengal, India. Prior to the SWASV experiment, the sample
15 was treated with a filter to remove any insoluble contaminants. The water sample was then diluted
16 with concentrated HCl to adjust its pH value to 3 and no further sample treatment was done. The
17 standard addition of As^{3+} is performed to calculate the concentration of As^{3+} in the real sample.
18 The SWASV response and the corresponding calibration plots are shown in Figure S5 and the As^{3+}
19 concentration in the real sample is calculated as 2.24 ppb. To determine the validity of the
20 electrochemical method we discussed, recovery experiments are also performed with the real
21 sample in which a known amount of As^{3+} is added. The obtained recovery is varied between 90%
22 to 110% which indicates the RM-rGO₈ nanocomposite has a great practical application.

23 There are many factors that can influence the EC behavior of RM-rGO NCs, such as surface
24 morphology, the active surface area for EC reaction, the fraction of sp^2 bonded carbons come in
25 contact with the electrolyte, etc. The optimization of milling time is another aspect that requires
26 further analysis in terms of identifying the morphological, chemical and physical changes. In
27 addition, the shift in the peak current (anodic/ i_{pa} and cathodic/ i_{pc}) response and peak potential
28 difference (ΔE_p) in the CV i -E curve may be correlated to the surface oxygen functionalities and
29 the exposed edge planes of sp^2 bonded carbons. In order to identify the factors responsible for the
30 strong EC sensing results, XRD, Raman and FTIR spectroscopic tools are employed.

To determine the different phases present in the as obtained RM and synthesized RM-rGO NCs, XRD measurements were carried out and are represented in Figure 5a. In case of rGO, a broad diffraction peak around $2\theta \sim 25^\circ$ and a small peak at $2\theta \sim 43^\circ$ can be seen (Figure 5a(i)) which signifies the formation of rGO with less oxygen functionalities.³⁴ Whereas, in RM and all RM-rGO NCs, a mixture of many metal oxide phases such as hematite, goethite, calcite, and silica can be observed. However, hematite ($\theta \sim 12.06^\circ$, 16.57° , 17.80°) is the main dominant phase in RM which is expected due to the red color of the RM and it constitutes around 55% of the RM.³⁵ The reduction in particle size via ball milling can also be correlated with the XRD peak broadening with milling hour. Notably, in all RM-rGO NCs, the broad diffraction peak of rGO can be observed, indicating that rGO sheets are attached to the RM particles.

Raman measurements were also carried out to examine the phase purity and different vibrational modes present in the NCs. A series of band related to the different modes of vibration of metal oxides, e.g; E_g (~ 291 and 404 cm^{-1}) and A_{1g} (~ 223 and 502 cm^{-1}) mode of hematite (Fe_2O_3) phase; E_g ($\sim 146\text{ cm}^{-1}$) and A_g ($\sim 662\text{ cm}^{-1}$) mode of ilmenite (FeTiO_3) phase; E_g ($\sim 152\text{ cm}^{-1}$) mode corresponds to the calcite (CaCO_3) phase can be seen in the Raman spectrum of RM (Figure 5b(i)).³⁵ Raman spectrum of rGO and RM-rGO NCs display a typical characteristic peak of D and G band around 1345 and 1595 cm^{-1} , where D peak corresponds to the rGO sheet defects and G peak is related to E_{2g} phonon modes of the sp^2 bonded carbon. The relative intensity ratio of these two bands (I_D/I_G) is a simple way to quantify the degree of disorder present in the graphene sheet. In case of rGO, the ratio of the I_D/I_G is 1.00 and the value is increased to 1.13 for the RM-rGO₈ sample, which implies that the physical force during the milling process introduces defects and disorder to the graphene cluster. Further milling up to 12 hr. did not change much the value of I_D/I_G that indicates, rGO sheets are attached well to the RM particles which help graphene sheets to damage further.

Furthermore, FTIR spectroscopy examines the deoxidation of rGO and the presence of chemical bonds or attached functional groups in RM and RM-rGO NCs. In the case of rGO (Figure 5c(i)), the peak at 1560 cm^{-1} and a weak signal around 1685 cm^{-1} is referred to as the C=C and C=O stretching vibration respectively. However, other oxygen-containing functionalities such as epoxy or alkoxy groups (C-O) are completely absent in rGO which are the common features of graphene oxides FTIR spectra.³⁶ This observation confirms that most of the oxygen-containing functional groups are removed from the graphene sheet during the reduction process. On the other

1 hand, RM shows a strong absorption band around 595 cm^{-1} and a weak peak near 1645 cm^{-1} due
2 to the stretching vibration of Fe-O bonds of the hematite phase.³⁷ In addition, the presence of
3 goethite ($\sim 803\text{ cm}^{-1}$), characteristics bands correspond to the Si-O vibrations ($\sim 990\text{ cm}^{-1}$), presence
4 of CO_3^{2-} ($\sim 1420, 866\text{ cm}^{-1}$) groups are also detected. The positions and absorption bands of RM-
5 rGO NCs (Figure 5c(iii-v)) are nearly similar to that of RM. The rGO sheets are likely anchored
6 to the nano RM particles through carboxylate bonds (Fe-C-O) and the existence of which is
7 confirmed in the FTIR spectra (band around 1580 cm^{-1}) of RM-rGO NCs.³⁸ The existence of some
8 additional bands in the hydroxyl stretching region ($\sim 3300\text{-}3500\text{ cm}^{-1}$) can also be seen in RM-
9 rGO NCs. These attached hydroxyl functional groups in the RM-rGO NCs are advantageous for
10 adsorbing toxic metal ions.¹³

Figure 5 (a) XRD pattern (b) Raman spectra and (c) FTIR spectra of (i) rGO (ii) RM (iii) RM-rGO₄ (iv) RM-rGO₈ and (v) RM-rGO₁₂.

Thus, the key feature for the excellent EC performance is related to the high adsorption capability of the hematite phase rich RM. The formation of nano RM via mechanical milling increases the active surface area to adsorb As³⁺ ions while the presence of sp² bonded carbons in the rGO sheets is responsible for enhanced electron transport kinetics. The superior EC behavior of RM/rGO₈ and RM/rGO₁₂ can be attributed to the large active surface area of these NCs where RM particles are properly surrounded by the rGO sheets and larger fraction of sp² carbon comes in contact with electrolyte during EC measurements. In addition, the attached functional groups (hydroxyl and carboxylic) to the NC surface not only serve as active sites for electrodeposition of As³⁺ ions but also act as a bridge for rapid electron transfer from solution to electrode surface. Therefore, the NCs prepared at longer milling hour (>4) with exposed sp² carbon and less oxygen functionalities facilitates the electron transfer kinetics. The combined effect of RM and electrically conductive rGO allows more effective electrodeposition of As³⁺ ions on the NCs surface, which in turn improves the EC sensing performances.

CONCLUSIONS

In a time of high demand of low-cost potential nanomaterial for environmental carcinogenic detection, this work successfully demonstrates the applicability of mechanically milled RM-rGO NCs as a working electrode material for sensitive and efficient electroanalysis of toxic As³⁺ ions. The electrode (RM-rGO₈) can accurately detect As³⁺ in the presence of other interfering metal ions namely Cd²⁺, Cr²⁺, Zn²⁺, Cu²⁺, Pb²⁺, and Hg²⁺. Mechanical ball milling offers a uniform morphology and enhanced charge transfer kinetics from the low-cost industrial waste RM. However, the optimization of ball milling time is considered to be the key factor to achieve the desirable EC sensing platform. The improvement in the EC performance of RM-rGO NCs with milling time can be attributed to the formation of functionalized RM-rGO NPs which not only provide the large no of active sites for As³⁺ adsorption but also accelerate the electron transport kinetics.
