Abstract

Multi-layered structured organic particles have had an extensive impact on a wide array of biomedical applications not limited to drug delivery, imaging and biosensing. A tri-needle coaxial electrospraying system was utilized to engineer multi-layered polymeric particles in a one-step, facile process at ambient temperatures. The effect of the dominant processing parameters on the development of a conical cusp that eventually ejects an ultrathin liquid ligament were firstly explored here. Subsequently, the validation of the intermediate solutions that possessed different conductivities on stabilizing jetting modes and the resulting particle morphology was also investigated. Polycaprolactone (PCL) solutions with different molecular weights were selected as the outer layer using fluids with various conductivities. Five different formulations were studied as the intermediate layers: PCL in acetic acid, ethyl cellulose in acetic acid, ethyl cellulose in dichloromethane, ethyl cellulose in ethanol and silicone oil and polyvinyl pyrrolidone in water. The results systematically demonstrated that the processing parameters (type of polymer, polymer molecular weight, solution concentration, flow rate, applied voltage and collector distance) play a significant role in the formation of the stable Taylor cone. This study further identified that the coaxial arrangement of three needles successfully produced multi-layered microspheres with uniform size distribution.

1. Introduction

The engineering and development of organic particles has yielded many opportunities to address and treat many challenging medical conditions. The use of polymers in particulate form has exponentially increased in recent years, especially as contrast agents and sensors.^{1, 2} Successful encapsulation of multiple drugs has been of great interest, especially in cases where patient compliance and advanced therapy is crucial. For example, a combination of anti-inflammatory and anti-cancer drugs is promising for cancer therapy as both the inflammation and prevention of further tumor development can be targeted^{3, 4}. By encapsulating two or more actives in one dosage can deliver synergistic therapeutic effects and reduce unwanted side effects⁵.

Microparticles with various morphologies and functions have attracted widespread attention in biomedical fields. Their uses have extended to serving as drug carriers for oral capsules or injectable agents, providing an adequate environment for 3D cell culture and acting as a platform for multimodal imaging and therapy⁶⁻⁸. Functionalities of the particles largely depend on their surface morphology and internal structure^{9, 10}. Due to the possibilities of fabricating microparticles with unique morphologies, the development of new and complex functionalities has also arisen^{11, 12}. For example, polymeric hollow particles with pores can be readily used to load actives for an array of applications such as film coatings, drug delivery systems, catalysts, crystals, for chemistry, biotechnology, and materials science¹³. Several methods have been utilized for synthesizing such composite particles however most of these approaches are multi-step processes; requiring additional reaction conditions such as inert gas or maintaining reaction temperatures or using elevated processing temperatures or pressure^{14, 15}. As a result, there are some hurdles when attempting to continuously produce multi-layered particles for in line production. In addition to this, current research demonstrates that

only polymeric materials with appropriate biosafety, biocompatibility, and biodegradation are considered for particle engineering; limiting the selection of polymers that can be used with these methods.¹⁶

The electrospraying technique is a one-step preparation method which has been widely used to engineer particles on micro and nano scale^{17, 18}. The diameter and surface morphology of resulting particles is regulated by process parameter manipulation (i.e. flow rate, applied voltage and collector distance)^{19, 20}. Tri-needle coaxial electrospray is a facile and versatile method which has been used to produce multilayered (more specifically tri-layered) polymeric particles in a one step process which is operated at ambient temperature²¹. This engineering method allows particles to be collected with a solvent, proving to be a cost-effective and convenient way of yielding porous polymeric particles. Although the tri-needle electrospraying technique can be exploited in preparing composite structure with multiple layers; stable Taylor cone formation is crucially affected by different parameters and material and/or solution characteristics²²⁻²⁴. Therefore, in this study, we comprehensively explored fundamental conditions of achieving a stable co-jetting mode during the tri-axial electrospray process by investigating the effects of processing parameters (type of polymer, polymer molecular weight, solution concentration, flow rate, applied voltage and collector distance) on the formation of Taylor cone and its downstream impact on particle size distribution and morphology.

Polycaprolactone (PCL), a FDA approved biomaterial, is a synthetic biocompatible polymer with excellent biodegradability, spinnability, good mechanical properties. It has been widely used to engineer particles with various structures for numerous biomedical applications²⁵. Dimethyl silicone oil has also shown its potential in coaxial electrospraying due to its advantageous viscosity and stable chemical properties. Ethyl

cellulose (EC) and polyvinylpyrrolidone (PVP) can be processed via the multi-needle electrospray technique with PCL due to their immiscibility. In this study, PCL was employed as the inner and outer layers while silicone oil, EC or PVP as the formed the intermediate layer. The effect of polymer molecular weight and the dominant processing parameters on the stability of jetting mode and the morphology of the sprayed products were systematically explored.

2. Materials and Methods

2.1. Materials

Poly-caprolactone (PCL) with different molecular weights (Mw: 14000, 45000, 80000 g/mol), polyvinylpyrrolidone (PVP) with a molecular weight of 10000 g/mol, and rhodamine B were obtained from Sigma-Aldrich (St. Louis, USA). Dimethyl silicone oil, ethyl cellulose (EC), and Nile red were purchased from Aladdin Chemistry Co., Ltd (Shanghai, China). Dichloromethane (DCM), ethanol, and glacial acetic acid (HAc) were received from Sinopharm Chemical Reagent Co., Ltd (Shanghai, China). Deionized water (DI water) was produced with a Millipore Milli-Q Reference ultra-pure water purifier (USA). All chemicals were utilized without any additional purification.

2.2. Solution preparation

Briefly, the polymers were respectively dissolved into corresponding solvents, and placed on a magnetic stirring (VELP ARE heating magnetic stirrer, Italy) in a flask for 24 hours at 300 rpm at room temperature ($\sim 25^{\circ}\text{C}$) to achieve homogenous solutions. PCL (with different molecular weights: 14000, 45000, 80000 g/mol) was dissolved in HAc; PVP was dissolved in DI water; EC was dissolved in HAc, ethanol, or DCM. For mapping the jetting status and the formation of a stable Taylor cone during multi-fluid

processing, fluorescent dyes at concentration of 0.01 w/v% were added and stirred uniformly when preparing the middle solution. According to the dye's solubility, PVP solution was stained with rhodamine B, while other polymer solutions were stained with Nile red dye.

2.2. Characterization of physical liquid properties

The surface tension of the solutions were measured using an interfacial tensiometer (SK200KB, KINO Industry Co. Ltd., USA) based on pendant-drop method, using **Equation 1**^{26, 27}:

$$\gamma = \frac{g D_e^2 \Delta \rho}{H} \quad (\text{Equation 1})$$

where γ is the surface tension of the solution, $\Delta \rho$ is the density difference between the solution and air, D_e is the maximum diameter of the hanging droplet, H is the correction coefficient, which relates to the shape of droplet.

Solution density was measured using a pycnometer and **Equation 2**:

$$\rho_x = \frac{m_x - m_0}{V_0} + \rho_0 \quad (\text{Equation 2})$$

where V_0 is the volume of the bottle, ρ_0 is the density of pure water, ρ_x is the density of the testing solution, m_0 is the total mass of the bottle filled with water, m_x is the total mass of the bottle filled with testing solution.

The viscosity of the polymeric solutions was measured using a viscometer (LVDV-II, Brookfield, USA). 2 mL of solution sample was added into stainless steel wells and the viscosity was measured at 25 °C, using a S21 spindle at 140 rpm. Electrical conductivity was measured with a YSI 3200 conductivity meter (YSI, USA) at 25 °C.

2.4. Fabrication of multilayered composite particles

The multilayered microparticles were engineered using a tri-needle electrospaying apparatus. As shown in **Figure 1**, the electrospaying system here consists of 3 coaxially arranged processing spinneret, a high voltage supply (Glassman high voltage Inc. series FC, USA), three syringe pumps (KD Scientific KDS100, USA), a charge-coupled devices (CCD) camera (Baumer TXG02C, Germany), and a grounded ring-shape electrode. The inner and outer diameters of the concentric needles were 0.50 mm and 0.31 mm, 1.60 mm and 1.07 mm, and 2.85 mm and 2.26 mm, respectively for the inner, middle and outer needle.

Figure 1. Schematic diagram of the tri-axial electrospaying system.

Solutions were drawn into 5 ml plastic syringes which were attached to the conductive needle tip using silicone tubing. The infusion rate was controlled using high-precision programmable syringe pumps. An electric field was introduced (maximum ~ 30 kV, 0.1 mA) between the tri-axial needle and ground electrode via a high voltage supply (Glassman high voltage Inc. series FC, USA). The ring-shape electrode with inner and

outer diameters of 2.7 cm and 3.5 cm was set directly below the tri-axial needle 5 mm away.

For investigating the influence of processing parameters, the collector distance was kept at 20 cm. 20 w/v% PCL dissolved in HAc was infused into the outer layer of the spinneret, when dimethyl silicone oil and 10 w/v% PCL solution were loaded into the middle and inner layers, respectively. The flow rates of the outer, middle and inner solutions were kept at 5.0, 1.5, and 0.8 mL/h, respectively while the applied voltage was kept at 12 kV. During the electrospraying process, the coaxially arranged set-up was observed using a high-speed camera.

2.5. Particles morphology observation

Optical microscopy (OM, Pheonix BMC503-ICCF, China) and field emission scanning electron microscopy (SEM, ProX, Phenom, Netherlands) were used to study the size and surface morphology of the resulting particles. For SEM analysis, samples were placed on a metallic stud using double-sided conductive tape and were subsequently sputtered coating with a layer of gold under vacuum (Ion sputter MC 1000, Hitachi, Japan) for 90 s at a current intensity of 25 mA. The micrographs were subsequently analyzed using ImageJ software (National Institute of Health, USA) to measure the mean particle diameter. The average diameter of the engineered particles was quantified 100 randomly sampled particles. All the statistical graphs were plotted using Origin software (OriginLab, USA). All the experiments were performed in triplicate and data is presented as mean $\pm$ standard deviation (n=3).

3. Results and Discussion

3.1. Jetting mode deformation upon altered voltage

A stable Taylor Cone is a pre-requisite for generating uniform electrosprayed particles²⁸. Here, 20 w/v% PCL (Mw=45000 g/mol) was dissolved in HAc and injected into the outer layer of the spinneret, when silicone oil and 10 w/v% PCL solution were infused into the intermediate and inner needles of the spinneret, respectively. The flow rates of the outer, middle and inner solutions were kept at 5, 1.5, and 0.8 mL/h, respectively. As shown in **Figure 2**, increasing the applied voltage from 0 kV to 20 kV, the droplet at the spinneret tip transitioned from dripping mode (**Figure 2a-2g**) to stable jetting (**Figure 2h-2n**) and finally to multi-jetting mode (**Figure 2o**).

Figure 2. Transformation of the Taylor cone during the electrospaying process by increasing the applied voltage from 0 to 20 kV. A stable cone jet was achieved at 12 kV, as indicated in (Figure 2k); multi-jet occurred when increasing applied voltage to 20 kV, as shown in (Figure 2o).

3.2. Effect of molecular weight of shell solution on jet flow and particle formation

The outer solution was the ‘driving liquid’ during the coaxial electrospaying process, due to the higher electric conductivity of the PCL solution (0.054 $\mu\text{S}/\text{cm}$) compared with the intermediate liquid (silicone oil) (as shown in **Table 1**). Hence, the outer PCL solution becomes the dominating force in the electrospaying process²⁹. As mentioned

earlier, to achieve uniform particles a stable cone-jet must be attained. The formation of this stable jet is synthetically influenced by gravity, applied electrical force and solution surface tension ³⁰. Liquid surface tension was significantly affected by molecular weight and concentration of the polymers. Hence, three different PCL molecular weights were used for the outer solution to investigate the effect of molecular weights of the outer polymeric solution on jetting mode and the resulting particle size distribution. Here, silicone oil and 10 w/v% PCL (Mw=45000 g/mol) solution were used as the intermediate and inner layer, respectively.

Table 1. Physical properties of solutions

Solute@Solvent	Concentration (w/v%)	Density (g/cm ³)	Conductivity (uS/cm)	Surface Tension (mN/m)	Viscosity (mPa·s)
EC@HAc	20	1.064	0.330	42.052	8454±29
EC@DCM	20	1.275	0.358	46.365	3839±76
EC@EtOH	10	0.826	20.570	34.783	1727±4
PVP@Water	20	1.035	1133.000	98.676	44±2
Silicone Oil	/	0.970	0.00	21.846	582±2
PCL@HAc Mw=14000 g/mol	10	1.050	0.053	43.033	59±1
PCL@HAc Mw=80000 g/mol	10	1.055	0.208	39.630	1136±4
PCL@HAc Mw=45000 g/mol	5	1.049	0.054	41.687	43±3
PCL@HAc Mw=45000 g/mol	10	1.053	0.051	31.606	133±1
PCL@HAc Mw=45000 g/mol	20	1.057	0.045	39.646	1002±3

As seen in **Figure 3a-c**, by simultaneously regulating the flow rate and applied voltage, a stable jet could be achieved using the parameters highlighted in green. The most versatile solution which achieved a large operating window when obtaining a stable jet contained PCL with molecular weight of 45000 g/mol (**Figure 3b**). The particles fabricated using this solution exhibited the largest diameter amongst the three groups of different PCL molecular weight (**Figure 3g**). **Figure S1** shows the optical and SEM images of particles generated with different PCL molecular weights. At low molecular weights (14000 and 45000 g/mol), insufficient particle solidification was observed with oil leakage which subsequently resulted in defective particle structure. **Figure 3f** shows that electrosprayed particles containing a high molecular weight (80000 g/mol) PCL shell successfully encapsulated the silicone oil whilst demonstrating the smallest average diameter ($49.29 \pm 13.21 \mu\text{m}$). Some fibrous structures can also be observed (**Figure S2**). These results demonstrate that the molecular weight of the outer solution significantly affects the jetting mode and subsequently plays an important role in particle morphology and size distribution.

As previously reported^{31, 32}, during single-needle electrospray, molecular weight of the solution influences the jetting status as shown in **Equation 3**:

$$(n_e)_{\text{solution}} = \frac{(\phi_p M_w)}{M_e} \quad (\text{Equation 3})^{31, 32}.$$

Here, $(n_e)_{\text{solution}}$ is the entanglement number of the polymer solution, ϕ_p is the volume of the polymer, M_w means molecular weight, and M_e presents the molecular weight of chain entanglement. $(n_e)_{\text{solution}}$ is proportional to the value of M_w .

With increasing $(n_e)_{\text{solution}}$, the electrosprayed products transformed from microparticles to particulate/fibrous matrixes and finally fibers. In accordance with this

both particles and fibers were observed using high molecular weight PCL. Based on this, in order to achieve a stable jetting mode and uniformity of solely particles, PCL with molecular weight of 45000 g/mol was selected for the following study.

Figure 3. Effect of molecular weight of shell solution on the jet flow and fabricated composite particles. (a)-(c) present the stable jetting range at different process parameters using PCL with molecular weight of 14000, 45000, and 80000 g/mol (solution concentration is 20 w/v% for all the groups). (d)-(f) show the size distribution of microparticles prepared with PCL solution at molecular weight of 14000, 45000, and 80000 g/mol, respectively. (g) diameter change as a function of PCL molecular weight.

3.3. Effect of shell solution concentration on jet flow and particle formation

The effect of shell solution concentration on jet mode and particle fabrication was assessed by altering the outer PCL solution concentration from 5 to 20 w/v%. Here, silicone oil formed the middle layer and 10 w/v% PCL formed the inner layer of the resulting particles. Stable jetting mode is defined here as a formation of steady Taylor cone in the absence of multi-jetting.

Figure 4a-c demonstrates a stable jet could be formed using the parameters within the green regions. This competent area of achieving a stable jet amplified with increasing polymer concentration, reaching the largest area at a concentration of 20 w/v%. This high concentration results in increased polymer chain entanglement subsequently causing an increase in solution viscosity from 43 mPa.s (5 w/v% PCL) to 1002 mPa.s (20 w/v% PCL). As shown in **Figure 4d-f**, with increasing outer PCL concentration, the diameter distribution of the resulting particles decreased; changing from being between 25-270 μm when using 5 w/v% PCL to 85-110 μm when using 20 w/v% PCL. Although these particles were generated by using tri-axial electrospraying, this phenomenon has been observed when using single needle electrospraying. This is thought to be because of the increase in solution concentration and how this allows for sufficient solvent evaporation and solidification of particles^{33, 34}. The electrosprayed samples when using 5% w/v PCL seem to be insufficiently dried droplets of non-spherical shape (**Figure S2a, d, g, j**). Increasing PCL concentration to 10 w/v%, microparticles were successfully fabricated however once collected the shape of the particles changed to show a more flattened morphology as a result of insufficient collection distance to allow complete solvent evaporation resulting in oil leakage

(Figure S2b e, h, k). When the concentration was further increased to 20 w/v%, spherical particles were obtained (Figure S2c, f, i, l). Whilst the theory of sufficient solvent evaporation causing reduced diameter distribution has been substantiated in previous studies, here the decrease in particle diameter could also be attributed to the successful encapsulation of the inner solutions at high shell concentrations. At low concentrations (5 and 10 w/v%), polymer entanglement between molecular chains was too weak to effectively encapsulate the intermediate and inner solutions.

Figure 4. Effect of shell solution concentration on jet flow and the fabricated composite particles. (a)-(c) present the stable jetting range at different processing parameters using PCL at the concentration of 5, 10 and 20 w/v%, respectively. (d)-(f) show the size

distribution of microparticles prepared with different PCL concentration. (g) Diameter change as a result of outer PCL solution.

3.4. Effect of process parameters on jet flow and particle formation

A multitude of process parameters have been proven to affect the electrospraying process and the fabrication of particles. The most crucial parameters that have been identified are applied voltage, flow rate and working distance (the distance between the needle exit and the collection plate).

The voltage that is applied to the system plays an important role in regulating the jet. The applied voltage must be strong enough to overcome the surface tension of the solution being processed and by atomizing the liquid, the emitted droplet size can be altered/controlled³⁵. Here, the voltage was maintained within the range from 9 to 18 kV with working distance being kept constant at 20 cm. The flow rate of outer, middle and inner solutions was kept at 5.0, 1.5 and 0.8 mL/h, respectively. The resulting particles were observed using optical microscopy and SEM, as shown in **Figure 5**. Operating the tri-axial electrospraying process at 9 kV proved to be insufficient due to the fabrication of solvent-rich structures; suggesting incomplete solvent evaporation and inefficacious jetting mode. Upon hitting the collector plate, the impact force caused the structures to flatten (**Figure 5a, e, i, m**), resulting in the leaking of the silicone oil and inner PCL solution. Increasing the voltage to 12 kV (**Figure 5n**), 15 kV (**Figure 5o**) and 18 kV, the topography of the particles became more prominent; becoming more defined, forming solid spherical structures when operating the process at 18 kV (**Figure 5p**).

Figure 5. Microparticles prepared using PCL solutions at different applied voltages. From left to right, the collector distances were 9, 12, 15, 18 kV, respectively. The top two lines (a-h) are the optical images presenting the particles size distribution, where the second row is zoom-in version of the first row. (i-p) are the SEM images, showing the surface morphology of the particles, where the bottom row of SEM images is a respective magnified view of electrosprayed particles shown above

Figure 6a-d shows the effect of applied voltage on particle diameter and size distribution. A much narrower diameter distribution was observed at higher applied voltage compared to when operating at a lower voltage (9 kV). It is clear to see from the SEM images and **Figure 6** that the collapsed structures seen at lower operating voltages gradually disappeared with increase in voltage. The morphology of the resulting particles transitioned from hemisphere structure to fully spherical particles

with smaller particle diameters. This variation trend can be seen in **Figure 6m**. The average particle diameter reduced from $91.6 \pm 30.3 \mu\text{m}$ to $33.1 \pm 16.3 \mu\text{m}$ when increasing the operating voltage from 9 kV to 18 kV, respectively. The applied voltage has a significant impact on jetting behavior; increasing voltage results in thinner electrohydrodynamic jet subsequently fabricating smaller droplets due to an enhanced stretching force.

Figure 6. Effects of process parameters on particle size distribution. (a)-(d) Size distribution of microparticles prepared with the applied voltage at 9, 12, 15, and 18 kV, respectively (flow rate was kept as 5.0, 1.5 and 0.8 mL/h for the outer, middle and inner layer, individually); (e)-(h) Size distribution of microparticles prepared at flow rates of 3, 5, 8 and 12 mL/h; (i)-(l) Size distribution of microparticles prepared with the collector distance at 10, 15, 20, and 25 cm. Diameter change tendency of the particles

with regulating the parameters: (m) applied voltage; (n) flow rate of the outer PCL solution; (o) collector distance.

To study the effect of flow rate, the outer PCL solution flow rate was varied between 3 and 12 mL/h while keeping PCL molecular weight constant at 45000 g/mol. The intermediate liquid (silicone oil) and inner liquid (10 w/v% PCL) were infused at a flow rate of 1.5 mL/h and 0.8 mL/h, respectively. 3 mL/h proved to be an excessively low flow rate for the shell solution which was ineffective to provide enough liquid to encapsulate the inner oil (**Figure S3a, e, i, m**). It was found that spherical particles could be achieved when flow rate of the shell solution was increased to 5 mL/h. The outer solution successfully encapsulated the inner material effectively, fabricating well-structured microspheres with no oil leakage (**Figure S3b, f, j, n**). By further increasing the flow rate of the shell solution to 8 and 12 mL/h, it was found that the solvent in the outer fluid could not volatilize resulting in deformed, flat particles on the collector plate (**Figure S3o and p**).

Flow rate optimization for internal and external liquids in co-axial electrospraying is crucial when needing to preparing core-shell particles. Diameter distribution of the resulting particles fabricated using various shell solution flow rates is shown in **Figure 6e-h** with the variation trend being shown in **Figure 6n**. It was deduced that increasing the flow rate above 5 mL/h led to an increase in microparticle diameter. This is most likely due to the larger volume of solution being infused into the processing system resulting into insufficient atomization and solvent evaporation. A similar trend was also observed at 3 mL/h; due to the relatively low velocity, the outer fluid failed to effectively encapsulate the middle and inner layers resulting in loss of the silicone oil.

This subsequently resulted in increased particle diameter due to an enlarged core diameter and a relatively thinner shell under steady co-axial flow. Therefore, the outer flow rate was maintained at a higher flow rate than the inner to ensure sure the core could be sufficiently coated with the outer polymer shell [27]. Ding et al. have previously reported the applied voltage correlation between spraying nozzle and the electrode when engineering PCL microparticles [32].

In the present study, the effect of collection distance (distance from needle exit to ring-shaped ground electrode) on PCL core-shell microparticle fabrication using tri-axial electrospraying. The microparticles were prepared using different working distances: 10, 15, 20, and 25 cm while the applied voltage was fixed at 12 kV. At the collector distance of 10 cm, incomplete solvent evaporation was observed; resulting in significant oil leakage causing the electrosprayed structures to collapse rendering 10 cm too short an operating distance. Increasing the working distance to 15 cm and 20 cm, the resulting particles seem to acquire more spherical contours; with the impact force causing the shape to change and represent hemispherical morphologies. Further increasing the distance to 25 cm saw the fabrication of fully solidified particles, with a significant decrease in diameter, as shown in **Figure S4**.

Figure 6i-6l demonstrates that increasing the working distance from 10 to 25 cm leads to a change in diameter distribution. As the distance increases, the average diameter of the engineered particles decreased with the particle size distribution also narrowing. This may be attributed to the volatile solvent being given sufficient distance to evaporate before particle deposition on the collector plate; resulting in fully formed, dry spherical microparticles.

Figure 6o highlights the relationship between the mean diameter and the collection distance. When the increasing the working distance from 10 cm to 25 cm, the mean particle size reduced from $89.5 \pm 41.9 \mu\text{m}$ to $27.3 \pm 19.8 \mu\text{m}$, respectively. The decrease in particle size can be explained by a reduction in incomplete solvent evaporation (as the electrode distance increases); possibly resulting in particles with residual solvent which had not fully evaporated before reaching the collector.

3.5. Effect of the intermediate solution on the flow rate and microparticle formation

Compared with the co-axial electrospraying approach, microparticles prepared via tri-axial electrospraying contains 3 distinct layers: an inner core and an outer shell with an additional intermediate layer which is often designed to encapsulate bioactive components. It is important to note that the middle layer can affect the particle fabrication process. As a result, the effect of the composition of the intermediate layer (PCL@HAc, EC@HAc, EC@DCM, EC@EtOH, silicone oil and PVP@water) on the stability of the electro-jet and subsequent particle formation.

Jetting modes were recorded between the voltage range of 0-16 kV. Dripping, transition, and stable jetting modes are shown in **Figure 7**. All compositions of the intermediate layer except PVP@water demonstrated a stable jetting mode between 10 and 16 kV; showing good compatibility between all three layers of the multi-layered particles. When operating the electrospraying process when using PVP@water as the middle solution, stable jetting mode could only be achieved using a narrower voltage range; 10 – 14 kV. Using a higher voltage than this resulted in solution solidification at the processing needle exit. This may be caused by small sprayed droplets forming at the high voltage, expediting solvent evaporation and especially with increased PCL

concentration, a thin film formed in the outer layer of the particles inhibiting the formation of a stable jetting.

Figure 7. Effect of different intermediate solutions on Taylor cone formation during the tri-needle electrospaying process. As shown in the bottom row, PVP was stained with Rhodamine B, while for other combinations, polymer solutions incorporated staining with Nile red to distinguish distinct layers during the electrospay process.

The results collated here prove that when no significant solidification occurred with the inner and outer solutions, regardless of miscibility characteristics (i.e. PCL@HAc or silicone oil), a stable jet could be formed during tri-axial electrospaying process. While solidification happened either in the inner and outer layers, the jetting stability was found to be seriously affected; as seen when using PVP@Water as the middle layer solution. When there was no chemical interaction among the three solutions in the any of the three layers, the jetting stability is mainly dependent on the reaction among the

solvents in each layer with each solute. If there is some miscibility between the components within each solution, fluently stable jetting mode would be easily achieved.

As shown in **Figure 8**, when using dye rhodamine B to label the middle layer when PCL@HAc or EC@HAc was utilized, uniform microspheres were prepared. Here, the solutions in the inner/middle/outer layers were miscible and the fluorescent easily dispensed to the inner and outer layers from the middle layer. Therefore, no solid boundary was found among the three layers. While using EC@EtOH as the middle layer, ultrafine fibers co-occurring with the particles was observed. This was mainly due to the poor solubility of PCL in EtOH. When PCL dispersed from the middle layer to the inner and outer layers, PCL concentration increased leading to the formation of fibrous structures. Additionally, due to good electroconductivity ($20.57 \mu\text{S}/\text{cm}$) of the EC/EtOH solution, charging occurred at high applied voltage, facilitating the wide diameter distribution. When using EC@DCM as the middle layer, its conductivity ($0.385 \mu\text{S}/\text{cm}$) was higher than that of the inner ($0.051 \mu\text{S}/\text{cm}$) or outer layers ($0.045 \mu\text{S}/\text{cm}$). The driving liquid in the tri-axial electrospray process dominates particle formation. Due to the low boiling point of DCM, it evaporated rapidly, enhancing the solidification of the middle layer. However, non-uniform beaded fibers were obtained, as a result of protracted solidification in the outer layer. When PVP@water was selected as the middle layer, due to the blockage and unstable multi-jetting at the exit of spinneret, amorphous products were collected, including beaded fibers and particles with wide size distribution.

Leakage of the red dye (rhodamine B) identifying the middle layer also indicates the deformation of distinct tri-layered structures caused by the unstable jetting. In contrast, when silicone oil was selected as the middle layer, the products were uniform microspheres, with red marked middle layer, allowing the identification of definitive

core-shell structures with three layers. These results confirm that although jetting stability and jetting ability is dependent on a combination of interactions concerning gravity, electrical force and interfacial surface tension; the size and morphology of particles can be carefully controlled by modifying or altering various process parameters.

Figure 8. Effect of different intermediate solutions on microparticle formation and surface morphology.

Conclusion

This study explores the effects of dominant electrospraying processing parameters on jet formation and stability and particle morphology during tri-axial electrospraying. PCL was selected as the inner and outer layers, while using silicone oil, PVP or ethyl cellulose as the intermediate layer. The results successfully demonstrated that the material properties (polymer type, polymer molecular weight, solution concentration) and processing parameters (flow rate, applied voltage and collector distance) play a significant role in producing spherical microspheres with uniform size distribution. By modifying and regulating these processing parameters, a stable jetting mode can be achieved and multilayered microspheres with predesigned size and morphology can be successfully engineered for an array of applications in the pharmaceuticals remit.
