ABSTRACT: The intense conditions generated in the core of a collapsing bubble have been the subject of intense scrutiny from fields as diverse as marine biology and nuclear fusion. In particular, the phenomenon of sonoluminescence, whereby a collapsing bubble emits light, has received significant attention. Sonoluminescence has been associated predominantly with millimeter-sized bubbles excited at low frequencies and under conditions far removed from those associated with the use of ultrasound in medicine. In this study, however, we demonstrate that sonoluminescence is produced under medically relevant exposure conditions by microbubbles commonly used as contrast agents for ultrasound imaging. This provides a mechanistic explanation for the somewhat controversial reports of “sonodynamic” therapy, in which light-sensitive drugs have been shown to be activated by ultrasound-induced cavitation. To illustrate this, we demonstrate the activation of a photodynamic therapy agent using microbubbles and ultrasound. Since ultrasound can be accurately focused at large tissue depths, this opens up the potential for generating light at locations that cannot be reached by external sources. This could be exploited both for diagnostic and therapeutic applications, significantly increasing the range of applications that are currently restricted by the limited penetration of light in the tissue.

KEYWORDS: sonoluminescence, microbubbles, ultrasound, sonodynamic therapy

INTRODUCTION

Multibubble sonoluminescence is an intense thermal process whereby transient species formed during the collapse of bubbles under ultrasound (US) excitation (cavitation) emit light.1 The majority of previous studies on sonoluminescence have employed ultrasound frequencies and intensities that are significantly different from those used in diagnostic or therapeutic ultrasound.2–7 However, with the increasing use of microbubbles (MBs) in both ultrasound imaging and therapy,8 and studies showing sonoluminescence at ultrasound frequencies in the megahertz range,9–15 there is a need to understand whether these extreme events can, in fact, occur in the tissue.

In particular, sonoluminescence and the reactive oxygen species (ROS) associated with violent bubble collapse have been suggested as the means by which certain classes of drug can be activated by ultrasound,16–20 so-called sonodynamic therapy (SDT). Reports on SDT have demonstrated promising results for the treatment of aggressive and resistant tumor cell lines.21–23 This approach relies on the combination of ultrasound, ground-state molecular oxygen, and a “sensitizer” drug to produce cytotoxic reactive oxygen species in a targeted manner. Thus, SDT uses a similar approach to photodynamic therapy (PDT), a modality clinically approved for the treatment of superficial lesions and lesions that can be reached with an endoscope.24 Ultrasound can, however, be more tightly focused in deeper regions of human tissues compared to light, allowing SDT potentially to treat a wider range of lesions, compared to photodynamic therapy.

The initial findings of drug activation using ultrasound were reported in 1989,17 and since then, a range of sensitizers have been investigated.22,23 Over the last decade, microbubbles have been shown to enhance SDT, and a correlation between SDT effects and cavitation has been established, but the underlying mechanisms responsible for sensitizer activation have remained uncertain. Several theories have been proposed, including sonoluminescence14,15 and pyrolysis,25 but a consensus has yet to be drawn. The aim of this study was to investigate whether sonoluminescence events occur during the excitation of phospholipid-coated microbubbles using ultrasound parameters previously shown to have a therapeutic effect in vivo,26–29 and whether these events could activate a known SDT sensitizer (Rose Bengal (RB)). Investigation was also made of the production of different types of reactive oxygen species to...
determine whether their formation could provide an alternative or complementary pathway for sensitizer activation via pyrolysis (please see the Supporting Information).

**EXPERIMENTAL SECTION**

**Microbubbles.** 1,2-Dibehenoyl-sn-glycero-3-phosphocholine (DBPC) was obtained from Avanti Polar Lipids Inc. (Alabaster, Alabama). N-(7-Nitrobenz-2-oxa-1,3-diazol-4-yl)-1,2-dihexadecanoyl-sn-glycero-3-phosphoethanolamine, 1,3-diphenylisobenzofuran (DPBF), triethylammonium salt, and singlet oxygen sensor green (SOSG) were purchased from Thermo Fisher Scientific. Rose Bengal, polyoxyethylene (40) stearate (PEG 40 S), chloroform, and ethanol were all obtained from Sigma-Aldrich Ltd. (Gillingham, Dorset, U.K.). Sulfur hexafluoride (SF₆) and oxygen (O₂) gases were purchased from The BOC Group (Guilford, Surrey, U.K.). SonoVue was purchased from Bracco Research (Geneva, Switzerland).

To produce the microbubbles, a mixture of DBPC and PEG40S dissolved in chloroform (9:1 molar ratio) was added to a glass vial to produce a 5 mL batch of microbubbles at a total concentration of 4 mg/mL. The sample was covered with a pierced parafilm and set on a hot plate at 50 °C for 12 h to evaporate the chloroform. Once all of the solvents evaporated, the dried lipid film was suspended in 5 mL of filtered deionized water for 1 h at 80 °C under constant magnetic stirring. The magnetic stir bar was then removed.

The lipid mix solution was sonicated at low intensity (QSonica Q125, 20 kHz, 3 mm probe tip, amplitude: 20%, 1 min) with the sonicator probe tip immersed in the solution. The sonicator probe tip was moved to touch the air-water interface, and a light flow of sulfur hexafluoride (SF₆) gas was added to fill the headspace of the sample vial. The sonicator was then turned on at high intensity (amplitude: 80%, 20 s). The samples were capped and cooled on ice for 10 min, after which a layer of foam at the top of the sample and a thick layer of densely packed microbubbles underneath the foam were visible. To produce O₂-filled microbubbles, a 1 mL sample of SF₆ MBs was sparged with oxygen for 2 min, as described in.30 SonoVue was prepared according to the manufacturer’s instructions.

Microbubble size and concentration were determined through an analysis of optical images as previous studies have confirmed the reliability of this method compared to particle-sizing devices.31 For this, the microbubble suspension was diluted 1:20 in phophate-buffered saline and 10 μL was loaded onto a hemocytometer with a cover slide. Microscope images (30) were acquired through an optical microscope (Leica DM500 optical microscope, Larch House, Milton Keynes, MK14 6FG, U.K.) with a 40× objective lens at room temperature. The images were then analyzed using a purpose-written MATLAB code (R2016b, The MathWorks, Natick, MA) to determine microbubble mean size and concentration. For all experiments, microbubbles with a modal diameter of 2.1 ± 1.6 μm (Figure S1) were used, corresponding to the agents used in ultrasound imaging and therapy. These were also diluted to 5 × 10⁵ microbubble/mL in deionized water to reflect the concentrations that would be present in the human blood stream following injection.

**Exposure Chamber.** A chamber was designed and built for the characterization of sonoluminescence events to enable simultaneous measurements of photon and acoustic emissions from ultrasound-excited microbubbles. This consisted of a cube, made of black Delrin to minimize external light contamination, with an internal volume of 100 mL (Figure S1). The base of the chamber was coated with an ultrasound-absorbing material (F28, Precision Acoustics, Dorset, U.K.) to avoid the formation of standing waves. Ports in the walls enabled coalignment of the foci of two optical lenses (ACL25416U-A, Ø = 2.54 cm, f = 16 mm, NA = 0.79, ThorLabs, Ely, U.K.) and two ultrasound transducers at the center of the chamber. Photons were detected using two photomultiplier tubes (PMTs, Hamamatsu H10493-03, Welwyn Garden City, U.K.) coupled to the lenses. The first ultrasound transducer (1 MHz center frequency, 16 mm element diameter with an integrated drive system, Sonidel SP100, Dublin, Ireland)
was used to transmit ultrasound to excite the microbubbles. The second transducer (7.5 MHz center frequency unfocused, element diameter 1.25 cm, Olympus V320, Southend on Sea, U.K.) was used to passively receive nonlinear acoustic emissions indicative of cavitation activity. A schematic of the setup and associated instrumentation is shown in Figure 1.

**Experimental Protocol**. Sonoluminescence events were investigated in aqueous solutions ± MB, ± Rose Bengal. Samples were prepared in filtered deionized water to obtain 5 × 10^6 MB/mL as above and 2.5 μM RB. Samples were injected into the chamber via the filling port and exposed to ultrasound for 2 mins (1 MHz center frequency, 3.5 W/cm² temporal peak average intensity, 30% duty cycle, 100 Hz pulse repetition frequency) during which period 1000 photomultiplier tube (PMT) acquisitions were recorded. The first PMT was used to measure overall light emissions. The second was used with appropriate filters to measure sonoluminescence at specific wavelengths. The corresponding acoustic emissions were recorded using the 7.5 MHz center frequency transducer. A 2 MHz high-pass filter was used to remove the drive frequency from the recorded passive cavitation detector traces before preamplifying (SR445A, SRS, Sunnyvale, CA), digitizing it (Handyscope HS3, TiePie Engineering, Sneek, Netherlands), and saving it on a computer drive for analysis. The effect of bulk temperature was examined to determine if sonoluminescence could occur at biologically relevant temperatures.

For this, experiments were conducted with a sample temperature of 10, 23, and 37 °C, monitored using a PCE-T390 digital thermometer from PCE Instruments, before and after ultrasound exposure.

**Detection of Reactive Oxygen Species**. The detection of singlet oxygen specifically was accomplished using the commercial product: singlet oxygen sensor green (SOSG), which reacts with O₃ to form SOSG-endoperoxides with a strong fluorescence emission of around 525–536 nm. The less specific detection of both O₂ and/or O²⁺ was determined through a decrease in the absorbance of 1,3-diphenylisobenzofuran (DPBF) at 410 nm as it oxidizes in the presence of either species forming nonfluorescent 1,2-phenylenbis-(phenylmethanone). For the detection of hydroxyl radical, non-fluorescent benzoic acid was used as it becomes permanently fluorescent (Ex: 305 nm/Em: 420 nm) upon aromatic hydroxylation by •OH.

Fluorescence and absorbance measurements were done in quadruplets on COSTAR or Greiner UV-Star clear flat-bottom 96-well plates from Sigma-Aldrich (Dorset, U.K.), using a FLUOstar Omega multipurpose plate reader from BMG Labtech (Aylesbury, Bucks, U.K.) at room temperature. For some of the examination, these measurements were taken before and after sample exposition to determine a percent change in the intensity relative to the pre-exposure intensity. Sample absorbance measurements were all normalized to that of blank control.

**Data Analysis**. The acquired acoustic emission traces were fitted with a Tukey window to avoid discontinuities and then analyzed with a fast Fourier transform using MATLAB (R2017b The Mathworks, Natick, MA). The harmonics (multiples of the drive frequency ±100 kHz, ±2 MHz), ultraharmonics (half-integer harmonics of the drive frequency ±50 kHz, ±2 MHz), and broad-band (remaining signal > 2 MHz) components were extracted for each acquisition. The power and cumulative energy in these frequency subsets were calculated for each acquisition over the entire exposure time. To characterize the spectrum of the sonoluminescence, the signal of the filtered PMT was normalized with the total amount of light generated (Figure S1). This enabled a comparison between experimental runs. Each experiment was repeated n = 3 times. The fluorescence and absorbance readings were also performed four times for each sample. The average and the standard deviation within each group are presented.

#### RESULTS AND DISCUSSION

Measurements of sonoluminescence and acoustic emissions at 23 °C were made for microbubbles manufactured in-house with a sulfur hexafluoride (SF₆) or oxygen (O₂) gas cores and the commercially available contrast agent Sonovue (Figure S1). While all microbubbles tested produced sonoluminescence when exposed to US (Figure 2), reduced sonoluminescence counts were observed for O₂ microbubbles compared to Sonovue and SF₆ microbubbles. This was attributed to the lower stability of O₂ microbubbles and the higher solubility of O₂ in aqueous solutions compared to those of SF₆. The reduced broad-band energy levels produced by O₂ microbubbles (Figure 2) further confirmed these results. The pulse height distribution of individual sonoluminescence events was, however, found to be comparable between the formulations (Figure S2), highlighting that the cavitation of these systems generated comparable collapse conditions and sonoluminescence.

The spectrum of the light generated using SF₆ microbubbles was measured using a set of five optical filters at room temperature. Figure 3 shows a broad spectrum with an increased sonoluminescence generation at the lower wavelengths. As the intensity of sonoluminescence reported here was low, the use of a monochromator to obtain a higher-resolution spectrum was not possible.
wavelength resolution was not feasible, and thus specific molecular features in the optical spectrum were not discernible. However, sonoluminescence in water has been reported at 1 MHz with a broad continuous spectrum and no molecular features.\(^{12,33,34}\) Such broad spectra have been associated with radiation emissions from cavitation events, e.g., blackbody\(^{35}\) bremsstrahlung,\(^{35,36}\) and/or recombination radiations.\(^{37,38}\) Although no consensus has been reached on the exact mechanisms, the generation of reactive oxygen species (ROS) during microbubble cavitation such as hydrogen peroxide\(^{39}\) and hydroxyl radical\(^{40,41}\) concurs with the recombination radiation theory.\(^{12,38}\)

An increase in bulk solution temperature has been reported to affect sonoluminescence by (1) increasing the number of sonoluminescence events due to an increase in the number of cavitation events\(^{10}\) and (2) lowering the amplitude of individual sonoluminescence events due to lowering of the intensity of collapse.\(^{33}\) Measurements were taken at 10, 23, and 37\(^{\circ}\)C, and their comparison in Figure 4a shows the expected increase in sonoluminescence occurrence and broad-band activity at 37\(^{\circ}\)C when SF\(_6\) microbubbles were used as cavitation nuclei. As the amplitude of sonoluminescence was examined (Figure 4b), a decrease in the number of high-amplitude sonoluminescence events (>60 mV) was observed with higher bulk solution temperatures (Figure 4b inset). Thus, these results demonstrate that at biologically relevant temperatures, a greater number of sonoluminescence events occur when microbubbles are exposed to mild therapeutic US conditions; however, the amplitude of individual sonoluminescence events is reduced.

The generation of sonoluminescence by microbubbles and ultrasound is potentially of great importance for the fields of both photo- and sonodynamic therapies (PDT and SDT, respectively). In PDT, significant efforts have been made to design sensitizers with increased absorption at wavelengths that allow improved penetration of light in the tissue. Although the therapeutic effects of SDT have been reported since 1989,\(^{17}\) the explanation behind the activation of the sensitizer with this method was not well accepted. Therefore, we measured the sonoluminescence output with and without the presence of an absorbing sensitizer, in this case, Rose Bengal (RB). Figure 5a highlights that the presence of RB and SF\(_6\) microbubbles at 37\(^{\circ}\)C led to a decrease in sonoluminescence measured at the absorption wavelength of the drug (560 nm, Figure S3) compared to a reference wavelength (350 nm).

Hence, sonoluminescence from cavitating microbubbles can be absorbed by the surrounding sensitizers, leading to their activation. These results support the hypothesis that sonoluminescence and the resulting transfer of energy to an accepting sensitizer are a key mechanism underlying SDT and are consistent with the reports by Umemura et al.\(^{15}\) and Giuntini et al.\(^{14}\) at room temperatures and without the use of exogenously added cavitation nuclei. Additionally, Figure 5b shows that at the same ultrasound parameters, the combination of RB and SF\(_6\) microbubbles in solution produced significantly more singlet oxygen radicals compared to that of microbubbles alone, confirming the activation of RB.

In contrast, the presence of reactive oxygen species did not affect the activity of Rose Bengal at ambient temperatures and pressures (Figure S4), indicating that pyrolysis-induced ROS generation is not involved in the activation of Rose Bengal. Further, microbubble cavitation did not lead to significant degradation of Rose Bengal, demonstrating that significant pyrolysis of the sensitizer itself does not occur at these exposure conditions (Figure S5).

There are several aspects of these results that may be important for both diagnostic and therapeutic applications of ultrasound and microbubbles. In the absence of cavitation, ultrasound is a nonionizing modality, and epidemiological studies of ultrasound imaging have not identified any significant health hazards associated with the technique.\(^{42,43}\) Yet, bubble cavitation was shown to cause ionization of molecules as seen with a broad continuum of sonoluminescence, and the production of excited species and radicals.\(^{36,38}\) Here, we demonstrate that, in the presence of microbubbles, cavitation produces reactive oxygen species and sonoluminescence.

Figure 4. Sonoluminescence and broad-band acoustic emissions from SF\(_6\) microbubbles diluted in deionized water at 10, 23, and 37 \(^{\circ}\)C (\(n=3\), error bars indicate standard deviations for each run). (a) Total PMT counts above 6 mV in amplitude and broad-band energy for three different temperatures are displayed. (b) Number of PMT counts for increasing peak amplitude. Number of PMT counts in each bin is normalized by the total number of counts recorded in each run. The inset shows the sum of normalized PMT counts above 60 mV for each temperature tested. These results indicate that with increasing temperatures, while the number of cavitation events increases, their amplitude decreases. The sample temperature before and after ultrasound exposure did not fluctuate substantially (±1 \(^{\circ}\)C).
